(Received 7 December 2015; accepted 5 February 2016; published online 18 February 2016)

We grew heavily Mg-doped GaN using ammonia molecular-beam epitaxy. The use of low growth temperature (740 °C) allows decreasing the incorporation of donor-like defects ( $<3 \times 10^{17} \text{ cm}^{-3}$ ) responsible for  $p$ -type doping compensation. As a result, a net acceptor concentration of  $7 \times 10^{19} \text{ cm}^{-3}$  was achieved, and the hole concentration measured by Hall effect was as high as  $2 \times 10^{19} \text{ cm}^{-3}$  at room temperature. Using such a high Mg doping level, we fabricated GaN backward diodes without polarization-assisted tunneling. The backward diodes exhibited a tunneling-current density of  $225 \text{ A/cm}^2$  at a reverse bias of  $-1 \text{ V}$  at room temperature. © 2016 AIP Publishing LLC. [<http://dx.doi.org/10.1063/1.4942369>]

Interband tunneling has attracted a lot of interests in semiconductor physics and is a key component for various device applications thanks to the unique characteristics of negative differential resistance (NDR)<sup>1</sup> and electrical connection in series of  $p$ - $n$  junctions of disparate bandgap.<sup>2</sup> For III-nitride semiconductors, interband tunneling is useful to further improve the performance of optical devices, i.e., light-emitting diodes (LEDs),<sup>3,4</sup> vertical cavity-surface emitting lasers (VCSELs),<sup>5,6</sup> and multi-junction solar cells.<sup>7</sup> In principle, interband tunneling requires ultra-thin  $p$ - $n$  junction depletion width ( $w_d$ ) and therefore degenerates semiconductors. III-nitride compounds have suffered from a low tunneling probability ( $T_t$ ) due to the difficulty to get degenerate impurity doping and high potential-barrier heights ( $\Psi_{bi}$ ). Recently, GaN-based tunnel junctions (TJs) were achieved using polarization-assisted tunneling.<sup>8</sup> Those TJs exhibit current-voltage ( $I$ - $V$ ) characteristics with a backward-diode behavior, which shows a tunneling current at small reverse bias. GaN/AlN/GaN<sup>8</sup> and GaN/InGaN/GaN heterostructures<sup>9</sup> were proposed to take advantage of the high internal electric fields that builds up from the interfacial polarization-induced dipoles along the  $c$ -axis and which allows reducing  $w_d$ . However, an InGaN interlayer requires precise control of both the thickness and the indium compositions, and it could induce detrimental absorption losses in VCSELs. On the other hand, TJ devices with an AlN interlayer are hampered by a low reverse current density ( $<10 \text{ A/cm}^2$  at  $-5 \text{ V}$ ) due to the wide bandgap of AlN (6.05 eV). The realization of GaN TJs without polarization-assisted tunneling is thus of prime interest to take advantage of the full potential of GaN-based optical devices.

In ideal  $p$ - $n$  junctions,  $w_d$  is given by  $(2\epsilon_s\Psi_{bi}/q(N_A+N_D/N_A N_D))^{1/2}$ , where  $\epsilon_s$ ,  $N_A$ , and  $N_D$  are the permittivity ( $=9.8\epsilon_0$  for GaN using permittivity ( $\epsilon_0$ ) in vacuum),<sup>10</sup> the acceptor concentration, and the donor concentration, respectively. The relationship between  $N_A$  and  $w_d$  in GaN  $p$ - $n$  junction with  $N_D = 1 \times 10^{20} \text{ cm}^{-3}$  is shown in Fig. 1. As expected,  $w_d$

decreases with increasing doping concentration but even for high  $N_A$  values ( $>5 \times 10^{19} \text{ cm}^{-3}$ ) it remains below 10 nm without polarization-assisted tunneling. Under the Wentzel–Kramers–Brillouin approximation,  $T_t$  is given by<sup>11</sup>

$$T_t \cong \exp\left(-2 \int_0^{w_d} \sqrt{\frac{2m_t^* E_g x}{\hbar^2 w_d}} dx\right). \quad (1)$$

Here,  $m_t^*$  is the tunneling effective mass,  $E_g$  is the bandgap of semiconductors, and  $\hbar$  is the reduced Planck's constant. Assuming that for GaN TJs with polarization-assisted tunneling  $w_d$  equals the interlayer thickness, then  $T_t$  for GaN/2.8-nm-thick AlN/GaN<sup>8</sup> and GaN/6-nm-thick In<sub>0.3</sub>Ga<sub>0.7</sub>N/GaN<sup>9</sup> structures is estimated to be  $\sim 10^{-12}$  and  $\sim 10^{-18}$ , respectively. On the other hand,  $T_t$  of GaN TJs without polarization-assisted tunneling is much lower, typically  $10^{-33}$  for  $N_A = 5 \times 10^{19} \text{ cm}^{-3}$ . The dependence of  $T_t$  on  $N_A$  in GaN TJs without polarization-assisted tunneling is displayed in Fig. 1. From Eq. (1), we note that a high  $T_t$  requires small bandgap and/or thin  $w_d$ . In GaN-based optical devices,

FIG. 1. Depletion width and tunneling probability of a GaN  $p$ - $n$  junction calculated as a function of  $N_A$  for  $N_D = 1 \times 10^{20} \text{ cm}^{-3}$  using Equation (1).

<sup>a)</sup>Electronic mail: okumura.hironori.gm@u.tsukuba.ac.jp

TJs should be reversely biased thereby reducing  $w_d$  and significantly increasing  $T_i$  ( $> 10^{-20}$  at  $-1$  V). Nevertheless, superior backward-diode behavior does require thin  $w_d$  and therefore heavily doped GaN.

$p$ -type GaN epilayers can be grown by molecular-beam epitaxy (MBE) or by metal-organic vapor phase epitaxy (MOVPE). In both growth techniques, the conventional  $p$ -type dopant is magnesium, which acts as an acceptor by substituting for Ga sites. In Mg-doped GaN (GaN:Mg), the ionized acceptor concentration ( $N_A^-$ ) is intrinsically low due to the high ionization energy ( $E_a$ ) of Mg ( $\sim 185$  meV),<sup>12</sup> and because of compensation induced by inversion-domain boundaries and pyramidal defects in heavily Mg-doped GaN<sup>13</sup> and donor-like defects such as nitrogen vacancy ( $V_N$ ).<sup>14</sup> In addition, a post-growth process, e.g., a rapid thermal annealing (RTA), is required for  $p$ -type GaN grown by MOVPE to activate Mg acceptors from Mg-H complexes.<sup>15</sup> On the other hand, MBE growth of  $p$ -type GaN does not need RTA post-growth processes and the formation of compensation defects is hindered due to low growth temperature ( $\sim 750^\circ\text{C}$ ).<sup>16</sup> In this study, we report on the electrical properties of heavily Mg-doped GaN grown using ammonia MBE and on the demonstration of GaN backward diodes without polarization-assisted tunneling.

For all GaN growth, we used  $4\text{-}\mu\text{m}$ -thick GaN (0001) templates grown on 2-in.  $c$ -plane sapphire substrates by MOVPE. Before growth, molybdenum was deposited on the substrate backside using sputtering for heat coupling. GaN templates cleaved into half were loaded into the MBE chamber, followed by baking out at  $500^\circ\text{C}$  for 1 h in ultra-high vacuum to remove any residual surface contamination. The MBE chamber is equipped with effusion cells for Ga evaporation and purified ammonia gas to deliver the nitrogen species by on-surface cracking. We use N-rich growth regime, i.e., a high ammonia flow ( $> 50$  sccm) owing to the low thermal decomposition efficiency ( $\sim 4\%$ ) of ammonia.<sup>17</sup> After a  $1\text{-}\mu\text{m}$ -thick unintentionally doped (UID) GaN buffer growth, a  $0.5\text{-}\mu\text{m}$ -thick  $p$ -type GaN layer was deposited using an ammonia flow rate of 120 sccm (background pressure of  $1.2 \times 10^{-5}$  Torr in main chamber) and a Ga beam equivalent pressure (BEP) of  $3.4 \times 10^{-7}$  Torr. The growth rate was  $5.5 \pm 0.2$  nm/min. Mg  $p$ -type dopant was supplied by a Riber

VCOR 110 valved cell at  $250^\circ\text{C}$  and silicon  $n$ -type dopant by a conventional effusion cell. The Mg-doping concentration [Mg] was controlled by valve opening (BEP between  $0.9$  and  $4.2 \times 10^{-10}$  Torr). For GaN:Mg growth, low growth temperature ( $< 700^\circ\text{C}$ ) induces surface roughening due to Ehrlich-Schwoebel barrier at step edges on the surface.<sup>18</sup> On the other hand, higher growth temperature ( $> 750^\circ\text{C}$ ) leads to high compensation ratio of Mg acceptors, as defined by  $([\text{Mg}] - (N_A - N_D))/[\text{Mg}] > 20\%$ .<sup>16,19</sup> In this study, the GaN:Mg layers were grown at a temperature of  $740^\circ\text{C}$ .

The growth temperature and growth thickness of GaN were monitored using an optical pyrometer and spectral reflectance, respectively. During GaN growth, the reflection high-energy electron diffraction (RHEED) patterns were streaky, indicating two-dimensional (2D) growth mode. Impurity concentrations of GaN:Mg were determined by secondary ion mass spectrometry (SIMS) performed by Evans Analytical Group. Detection limits for hydrogen, carbon, oxygen, Si, and Mg are  $2 \times 10^{18}$ ,  $3 \times 10^{16}$ ,  $2 \times 10^{16}$ ,  $4 \times 10^{16}$ , and  $4 \times 10^{16} \text{ cm}^{-3}$ , respectively. The net acceptor concentration ( $N_A - N_D$ ) and hole concentration ( $p$ ) in the GaN:Mg layers were determined by electrochemical capacitance-voltage ( $C$ - $V$ ) measurements and by Hall effect measurements at room temperature, respectively. The ohmic contacts for the  $C$ - $V$  and Hall-effect measurements were obtained by metal indium paste and Pd (50 nm)/Au (200 nm) metal stack without RTA processes, respectively.

$N_A - N_D$  as a function of Mg flux for 500-nm-thick GaN:Mg layers is shown in Fig. 2(a).  $N_A - N_D$  linearly increases with Mg fluxes, suggesting efficient incorporation of Mg atoms into the GaN layers. We could control the lower limit of  $N_A - N_D$  to  $3 \times 10^{17} \text{ cm}^{-3}$ , indicating that the GaN:Mg layer has a fairly low concentration of compensation defects ( $< 10^{17} \text{ cm}^{-3}$ ). Notice that the concentration of oxygen and Si in GaN:Mg layers are under the detection limits. Actually,  $N_A - N_D$  agrees well with [Mg] measured by SIMS until a critical value of  $N_A - N_D = 7 \times 10^{19} \text{ cm}^{-3}$ . The  $N_A - N_D$  of  $7 \times 10^{19} \text{ cm}^{-3}$  is among the highest values reported so far for  $p$ -type GaN.<sup>12,20–22</sup> In ammonia MBE, the main donor-like native defects are supposed to be neutral  $Mg_{Ga} - V_N$  complex,<sup>23</sup> whose density increases with growth temperature. We speculate that the high  $N_A - N_D$  value of

FIG. 2. (a) Relationship between Mg flux and total acceptor concentration ( $N_A - N_D$ ) determined by capacitance-voltage measurements (white circle), and Mg flux as a function of Mg concentration determined by SIMS (black circle). (b) Room-temperature dependence of Hall concentration (white triangle) and Hall mobility (black triangle) on  $N_A - N_D$  for 500-nm-thick GaN:Mg layers. The line for Hall concentration represents the fit of the free hole concentration using Equation (2). The line for Hall mobility is a fit using  $\mu_{\min} + (\mu_{\min} - \mu_{\max})/(1 + (N_A - N_D/N_{\text{ref}})^\beta)$ ,<sup>24</sup> where  $\mu_{\min} = 1.0 \text{ cm}^2/\text{V s}$ ,  $\mu_{\max} = 36 \text{ cm}^2/\text{V s}$ ,  $N_{\text{ref}} = 1.5 \times 10^{19} \text{ cm}^{-3}$ , and  $\beta = 2.5$ .

$7 \times 10^{19} \text{ cm}^{-3}$  results from a reduction of these compensation defects by precisely controlling the growth conditions, i.e., a careful control of the growth temperature (740 °C), a large  $\text{NH}_3$  flow rate (200 sccm), and an optimized growth rate of 5.5 nm/min. By further increasing the Mg flux,  $N_A - N_D$  dramatically decreases, in agreement with previous works.<sup>16,22</sup> Further investigations are necessary to clarify the behavior of excess Mg atoms in MBE grown  $p$ -type layers.

The relationship between hole mobility and  $N_A - N_D$  below the critical concentration in 500-nm-thick GaN:Mg layers is displayed in Fig. 2(b). The hole mobility decreases with increasing  $N_A - N_D$ , as expected from ionized-impurity scattering. For GaN:Mg layer with  $N_A - N_D = 2 \times 10^{19} \text{ cm}^{-3}$ , the room-temperature resistivity, hole mobility, and hole concentration are  $0.2 \text{ } \Omega \text{ cm}$ ,  $13.5 \text{ cm}^2/\text{V s}$ , and  $2 \times 10^{18} \text{ cm}^{-3}$ , respectively. A hole concentration of  $2 \times 10^{19} \text{ cm}^{-3}$  is measured for GaN:Mg layers with the highest  $N_A - N_D$  value ( $= 7 \times 10^{19} \text{ cm}^{-3}$ ). This increase of the ionization efficiency for high [Mg] is due to a lower  $E_a$ .

$E_a$  of Mg acceptors can be estimated from the charge-neutrality conditions in a non-degenerate  $p$ -type semiconductor<sup>25</sup> and is given by

$$\frac{p + N_D}{N_A - N_D - p} = \frac{N_V}{g} \exp\left(-\frac{E_a}{k_B T}\right), \quad (2)$$

where  $N_V$  is the effective density of states in the valence band ( $2(2\pi m_h^* k_B T)^{3/2}/h^3$ ),  $g$  is the acceptor degeneracy (4 for GaN),  $k_B$  is the Boltzmann constant,  $T$  is the temperature (300 K), and  $m_h^*$  is the effective hole mass ( $1.25m_0$  for GaN).<sup>26</sup>  $E_a$  can be reduced in proportion to the average distance between ionized acceptors ( $\sim (N_A^-)^{1/3}$ ) due to binding energy reduction from Coulomb interaction with ionized acceptors and screening of the Coulomb potential by mobile charges.<sup>27,28</sup> We calculated a reduction of  $E_a$  from the Coulomb potential between ionized Mg acceptors and free holes using the equation of  $E_a = E_{a0} + fq^2(4\pi/3 \cdot N_A^-)^{1/3}/(4\pi\epsilon_s)$ , where  $E_{a0}$  is the acceptor ionization energy in the absence of ionized acceptors,  $q$  is the hole charge, and  $f$  is a geometric factor. The latter value for various semiconductors is almost constant ( $-1.6 \pm 0.1$ )<sup>29</sup> and should be mainly dominated by the attractive potential between mobile charges and fixed ions ( $-1.5$ ).<sup>27</sup> The experimental data were fitted under the assumption of  $N_D = 1 \times 10^{17} \text{ cm}^{-3}$  and  $N_A^- \approx p$ , as shown in Fig. 2(b). We used  $f = -1.69$  and  $E_{a0} = 195 \text{ meV}$ , close to the value (188 meV) estimated from the hydrogen-like impurity model ( $E_{a0} = 13.6\epsilon_0^2 m_h^*/(\epsilon_s^2 m_0)$ ). For GaN:Mg layers with a maximum  $N_A - N_D$  of  $7 \times 10^{19} \text{ cm}^{-3}$ ,  $E_a$  is as small as 29 meV. We conclude that the high hole concentration in GaN:Mg results from a high incorporation of Mg atoms and a screening of the binding energy of Mg acceptors.

Subsequently, we fabricated heavily doped  $n$ - $p$  junction diodes. The band diagram of the  $n$ - $p$  junction is shown in Fig. 3(a). We used a structure with thin  $n^{++}$  and  $p^{++}$  type GaN layers located at the  $n$ - $p$  interface to get rid of the detrimental effect of surface roughening and crystalline-quality degradation, which occurs in thicker layers. The structure of the  $n$ - $p$  junction devices consists of the following from the top: 50-nm-thick Si-doped GaN ( $N_D \sim 1 \times 10^{20} \text{ cm}^{-3}$ )/15-nm-thick

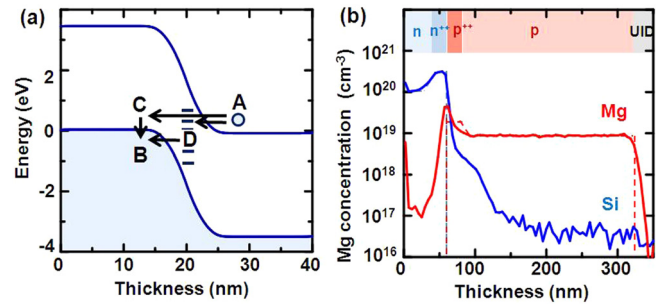

FIG. 3. (a) Energy band diagram of a heavily doped GaN  $n$ - $p$  junction ( $N_A = N_D = 1 \times 10^{20} \text{ cm}^{-3}$ ) at zero bias. For reverse and zero biases, carriers are tunneling in the depletion layer through path AB. At forward bias, some carriers might tunnel to local energy levels at C (path ACB) and at D (path ADB), causing excess current. (b) SIMS depth profiles of Si and Mg atoms in heavily doped  $n$ - $p$  junction of GaN. The detection limit of Si and Mg was equal to  $4 \times 10^{16} \text{ cm}^{-3}$  in both cases. The dotted line is expected doping concentration.

Si-doped GaN ( $N_D \sim 3 \times 10^{20} \text{ cm}^{-3}$ )/15-nm-thick Mg-doped GaN ( $N_A < 5 \times 10^{19} \text{ cm}^{-3}$ )/200-nm-thick Mg-doped GaN ( $N_A \sim 1 \times 10^{19} \text{ cm}^{-3}$ )/500-nm-thick UID GaN grown on GaN templates. High doping concentrations in  $n^{++}$  and  $p^{++}$  GaN layers were achieved by reducing the growth rate to 3 nm/min. We prepared a series of three  $n$ - $p$  junction structures with different Mg concentrations of  $2 \times 10^{19}$ ,  $5 \times 10^{19}$ , and  $1 \times 10^{20} \text{ cm}^{-3}$  in the  $p^{++}$  GaN layers without growth interruption at a constant growth temperature of 740 °C. The impurity concentration in the  $n$ - $p$  junction with Mg concentration of  $2 \times 10^{19} \text{ cm}^{-3}$  was determined by SIMS. Concentrations of hydrogen, carbon, oxygen, Si, and Mg in UID GaN were under the detection limits. As shown in Fig. 3(b), Si and Mg atoms were uniformly incorporated during growth. Both the Mg rise and decay signals had steep slopes of 7 and 6 nm/decade, respectively. The doping profile of Mg atoms at the  $n$ - $p$  junction interface exhibits a sharp peak, whose value of  $5 \times 10^{19} \text{ cm}^{-3}$  is higher than the expected Mg-doping concentration of  $2 \times 10^{19} \text{ cm}^{-3}$  and seems to slightly extend into the GaN:Si layer. This high Mg concentration is likely resulting from Mg surface segregation. On the other hand, the small tail of Si concentration of  $2 \times 10^{18} \text{ cm}^{-3}$  into  $p^{++}$  GaN may result from unintentional Si incorporation due to low growth rate. Al/Au (30/200 nm) stack was deposited for the  $n$ -type GaN contact using e-beam evaporation, followed by mesa isolation using  $\text{Cl}_2$  plasma in inductively coupled-plasma reactive-ion etching, and then evaporation of Pd/Au (30/200 nm) stack for the  $p$ -type GaN contact. Both  $n$ - and  $p$ -type contacts show ohmic characteristics. The typical resistivity of the  $n$ - ( $r_n$ ) and  $p$ -type ( $r_p$ ) contacts are estimated to be  $2 \times 10^{-5}$  and  $2 \times 10^{-3} \text{ } \Omega \text{ cm}^2$ , respectively, using transfer length measurement.

Room-temperature  $I$ - $V$  characteristics of the  $n$ - $p$  junction devices ( $50 \text{ } \mu\text{m} \times 50 \text{ } \mu\text{m}$ ) with  $[\text{Mg}] \sim 2 \times 10^{19}$ ,  $\sim 5 \times 10^{19}$ , and  $\sim 1 \times 10^{20} \text{ cm}^{-3}$  for the  $p$ -type layer are reported in Fig. 4(a). The devices with  $[\text{Mg}]$  ( $\approx N_A - N_D$ )  $\sim 2 \times 10^{19}$  and  $\sim 5 \times 10^{19} \text{ cm}^{-3}$  exhibit a backward-diode behavior, in which the reverse current is higher than the forward current at low voltage bias. The backward-diode behavior results from tunneling at reverse bias due to heavy  $p$ - and  $n$ -type doping levels. The tunneling-current density ( $J_T$ ) increases with  $N_A$  due to thinner  $w_d$ . For  $[\text{Mg}] \sim 5 \times 10^{19} \text{ cm}^{-3}$ ,  $J_T$  is  $225 \text{ A/cm}^2$  at a reverse bias of  $-1 \text{ V}$ . At higher  $[\text{Mg}]$  ( $\sim 1 \times 10^{20} \text{ cm}^{-3}$ , i.e.,

FIG. 4. (a) Current-voltage characteristics of GaN  $n$ - $p$  diodes ( $50 \times 50 \mu\text{m}^2$ ) for  $p$ -type layers with  $[Mg] \sim 2 \times 10^{19}$ ,  $\sim 5 \times 10^{19}$ , and  $\sim 1 \times 10^{20} \text{ cm}^{-3}$  at room temperature. (b) Current-voltage characteristics of GaN  $n$ - $p$  diodes ( $200 \times 200 \mu\text{m}^2$ ) for  $[Mg] \sim 5 \times 10^{19} \text{ cm}^{-3}$  for temperatures ranging between 150 and 450 K.

$N_A - N_D \sim 10^{18} \text{ cm}^{-3}$ ), both the reverse and forward current densities increase and the backward-diode behavior vanishes. The larger forward current density is attributed to excess current through energy levels within the forbidden bandgap of GaN. As shown in Fig. 3(a), defective  $p$ -type GaN layers (point C) and Mg surface accumulation induced defects at the  $p$ - $n$  interface (point D) may form energy levels in the  $p$ -type layer and at the  $n$ - $p$  junction interface, respectively, resulting in high carrier tunneling via ACB and ADB paths. Thus, the higher crystalline quality of  $p$ -type GaN would further improve the rectifying behavior of the backward diodes. The specific resistivity of the tunnel junction ( $r_{ij}$ ) is estimated to be  $2 \times 10^{-3} \Omega \text{ cm}^2$  using the total resistivity ( $r_t = r_{ij} + r_n + r_p$ ) obtained from the linear region of the reverse bias characteristics. Although  $r_{ij}$  is comparable with values reported in other reports,<sup>9,16</sup>  $r_{ij}$  is close to  $r_p$ . A reduction in  $r_p$  would thus further enhance  $J_T$ .

Temperature dependent  $I$ - $V$  curves of the  $n$ - $p$  junction devices ( $200 \mu\text{m} \times 200 \mu\text{m}$ ) with  $N_A \sim 5 \times 10^{19} \text{ cm}^{-3}$  are displayed in Fig. 4(b). At forward bias, the rectifying behavior is maintained over a large temperature range (150–450 K). A prominent metric for backward diodes is the curvature coefficient at zero voltage bias, defined as  $\gamma = (\partial^2 I / \partial V^2) / (\partial I / \partial V)$ .<sup>11</sup> Here  $\gamma$  is  $13 \text{ V}^{-1}$ , which is lower than the thermal limit value  $\gamma \sim q/kT \sim 39 \text{ V}^{-1}$  for the Schottky barrier. This may be ascribed to high  $n$ - and  $p$ -type doping concentrations. Notice that  $\gamma$  is constant ( $14 \pm 1 \text{ V}^{-1}$ ) over temperature variation up to 450 K due to the wide bandgap of GaN, like SiC backward diodes.<sup>30</sup> On the other hand, at reverse bias,  $J_T$  reduces with decreasing temperature due to larger energy bandgap. One should point out that signature of NDR is not observed even at low temperature. We suppose that thinner  $w_d$  using narrower bandgap interlayer and polarization-assisted tunneling is necessary for getting NDR and high  $J_T$ . Nevertheless, the  $J_T$  obtained in this work is  $\sim 1 \text{ kA/cm}^2$ , which is sufficiently high for applications in LEDs and solar cells. For instance, adding a TJ on top of an LED allows substituting the  $p$ -GaN layer by a transparent  $n$ -type GaN layer with much lower contact resistivity.<sup>5</sup>

In conclusion, we grew heavily Mg-doped GaN using ammonia MBE and demonstrated GaN backward diodes without polarization-assisted tunneling. N-rich growth regime at a low growth temperature of  $740^\circ\text{C}$  allows for low concentration of compensation defects ( $< 3 \times 10^{17} \text{ cm}^{-3}$ ).

Under these growth conditions, we achieved a high net acceptor concentration of  $7 \times 10^{19} \text{ cm}^{-3}$  and a high hole concentration of  $2 \times 10^{19} \text{ cm}^{-3}$  at room temperature while keeping high hole mobility. The corresponding resistivity is as low as  $0.2 \Omega \text{ cm}$ . Using such a high Mg doping level, we fabricated GaN backward diodes with a rectifying behavior over a large temperature range of 150–450 K. A tunneling-current density of  $225 \text{ A/cm}^2$  at a reverse bias of  $-1 \text{ V}$  at room temperature is measured, which is suitable for LED applications.

This work was supported by the CTI Project 10708.1 PFMN-NM and JSPS KAKENHI Grant No. 15H06070. We would like to acknowledge Dr. Raphaël Butté for critical reading of the manuscript.
